## Executive summary

Trans-Tasman Resources Limited (hereafter, TTR) plans to exploit a source of vanadium-titanomagnetite in South Taranaki Bight, New Zealand, with an offshore dredge-mining operation. Because this operation will displace, suspend and modify deep anoxic sediment, it may make sediment-bound contaminants available to pelagic and benthic biota.

To assess the potential of their mining operation for causing adverse effects, TTR contracted Auckland University of Technology (AUT) to investigate as a function of depth below the seafloor (1) selected physical properties of the target sediment, (2) the sediment content of acid volatile sulfides and simultaneously extracted trace metals, and (3) the concentrations of trace metals in suspensions of sediment in seawater. TTR also contracted AUT to investigate if grinding enriched iron sand increases the potential of this sand to release trace metals when suspended in seawater.

As expected for high-energy offshore environments, the low organic matter content (<1% dry weight) of the medium sand in the mining areas explained the low sediment content of acid volatile sulfides (AVS). We found no evidence for an increase with depth below the seafloor in sediment organic matter and AVS contents.

The concentrations of dilute-acid soluble cadmium, copper, lead and zinc in deep sediment were of the same order of magnitude as their maximum concentrations in surface (reference) sediment. For cadmium, copper and zinc, there was no evidence for consistent trend of increasing concentrations with increasing sediment depth below the seafloor. The sediment concentrations of lead decreased with depth below the seafloor at three of five sites. Overall, we infer a low probability of adverse effects of these dilute-acid soluble metals on benthic ecosystem functioning.

The concentrations of dilute-acid soluble chromium and nickel in deep sediment were often one order of magnitude higher than their maximum concentrations in surface (reference) sediment. Furthermore, at four of five sites, chromium and nickel concentrations increased with increasing depth below the seafloor. Additional analyses of sediment slurry collected to a maximum depth below the seafloor of 18 m, however, did not reveal evidence for such trend. We found no consistent increase with depth in the concentrations of dissolved nickel in the slurry. The concentrations of chromium in the slurry were below the detection limit.

For all metals except nickel, the concentration in seawater suspensions of deep sediment (elutriate) were either below detection limit (chromium, copper, lead, zinc) or, if a metal was detected (cadmium), the concentration did not exceed the ANZECC & ARMCANZ guideline for the protection of 99% of species. The detection limit of copper was below the guidelines for the protection of 95% of species.

The concentrations of nickel in the seawater suspensions of deep sediments (all five sites) and surface (reference) sediment (three of five sites) were equal or larger than the ANZECC & ARMCANZ guideline concentrations for the protection of 99% of species. However, the nickel concentration never exceeded the guideline concentrations for the protection of 95% of species. Assuming that the nickel concentration in South Taranaki Bight seawater equals the detection limit for nickel, it would only require an 83-fold dilution of the elutriate extract to decrease the highest nickel concentration measured to below guideline concentrations for the protection of 99% of species.

A sample of magnetically enriched iron sand was ball milled to three average sizes, 276  $\mu\text{m}$ , 183  $\mu\text{m}$  and 23  $\mu\text{m}$ . The average concentrations in this iron sand of dilute-acid soluble chromium, nickel and zinc decreased after each of the first two grinds but increased after the third grind to 171, 150, and 162% of that in the extract of the as-received enriched iron sand. In contrast, for copper and lead, the average concentrations in the extracts of the first two grinds did not significantly differ from that of the as-received iron sand but the third grind increased these concentrations to 193 and 132% of the concentration in the extract of the as-received iron sand. The concentrations of dilute-acid soluble cadmium were below reporting limits in both as-received and ball-milled magnetically enriched iron sand.

We conducted elutriate tests with magnetically enriched and ball milled iron sand to investigate if grinding of iron sand will increase trace metals concentrations in the seawater that feeds the iron sand through TTR's grinding mills. These tests revealed concentrations of cadmium, lead and nickel below the limits of reporting for all sediment samples. Chromium was detected only in elutriates of the fine sediment fraction; zinc was detected in elutriates of all sediment samples. For both metals, the concentration averages for each sand size fraction did not exceed the ANZECC & ARMCANZ guideline for the protection of 99% of species. We infer a low probability of adverse effects of these metals on ecosystem functioning of the South Taranaki Bight water column.

The concentration of copper in seawater suspensions of the enriched iron sand was negatively linearly correlated ( $r = -0.89$ ) with the size of the suspended iron sand particles. The average elutriate copper concentrations of as-received and the coarse iron sand fraction exceeded the ANZECC & ARMCANZ guideline for the protection of 99% of species. Assuming that South Taranaki Bight seawater contains 0.25 ppb copper an only 20-fold dilution would decrease this concentration to below the concentration limit for the protection of 99% of species. In contrast, the average copper concentrations in elutriates of medium and fine coarse iron sand exceeded the guideline for the protection of 80% of species. Here, a 160-fold dilution would decrease these concentrations to below the concentration limit for the protection of 99% of species.

# Introduction

Trans-Tasman Resources Limited (hereafter, TTR) plans to exploit a source of vanadium-titanomagnetite in South Taranaki Bight, North Island, New Zealand (Fig. 1), combining an offshore dredge-mining operation with an offshore beneficiation plant. Vanadium-titanomagnetite is a black iron ore that comprises vanadium pentoxide ( $V_2O_5$ ), titanium oxide ( $TiO_2$ ), and magnetite ( $Fe_3O_4$ ), a form of iron oxide with natural magnetic properties. It originates as crystals in volcanic rocks, washed down rivers, largely from Mount Taranaki but also from the Central Plateau of the North Island, to Taranaki Bight (Carter 1980). Specialised steel mills use vanadium-titanomagnetite to manufacture steel, either as a blend with other ores, e.g., haematite, or as a dedicated steel-making feed.

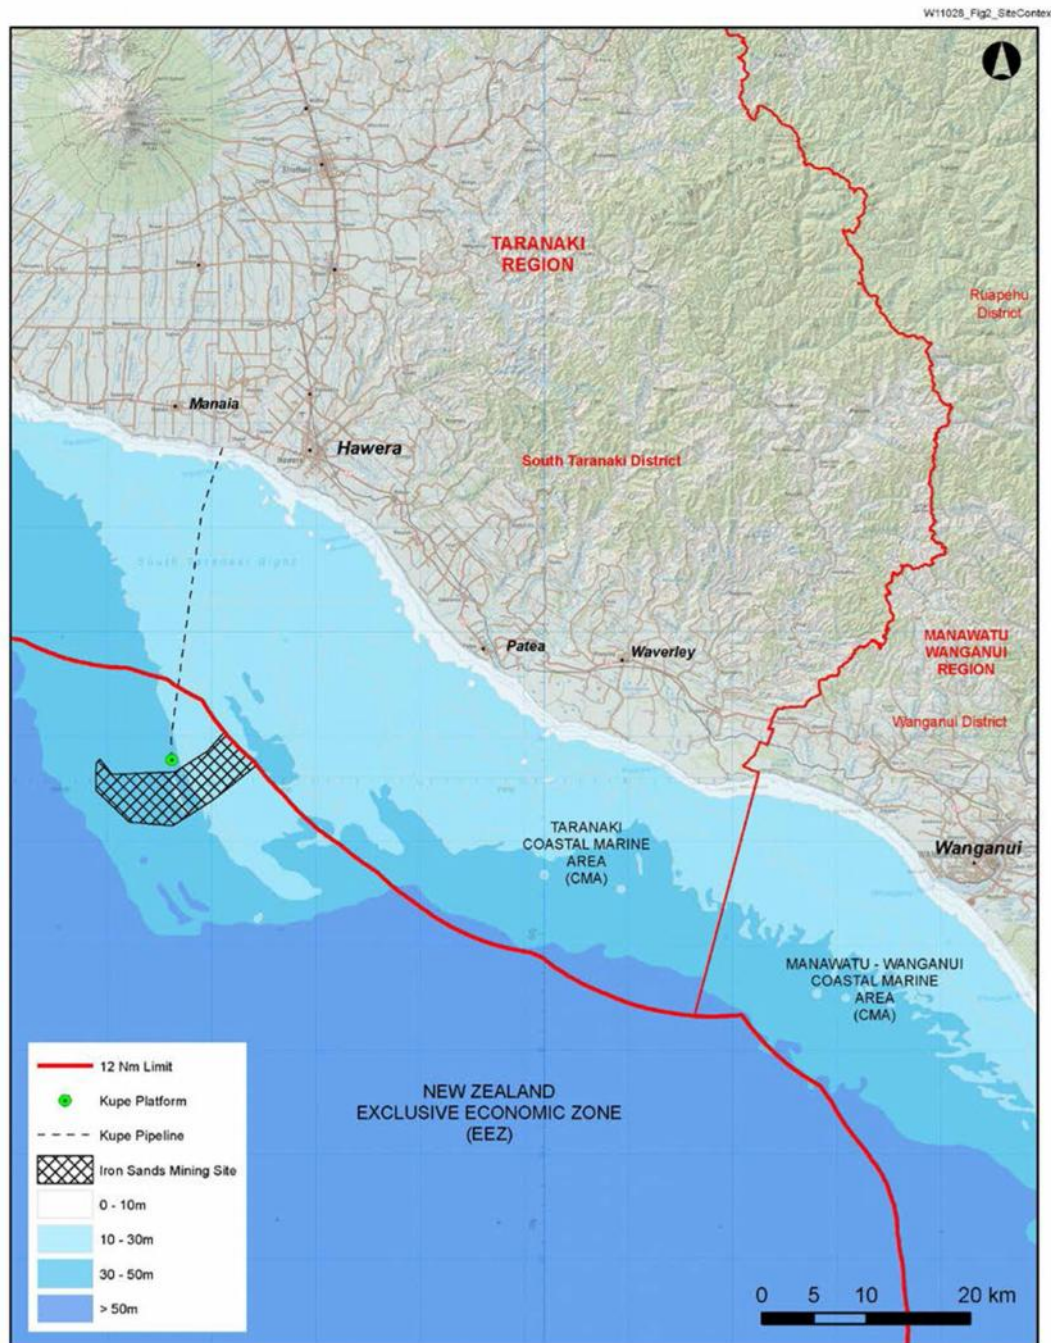

To source iron sand from South Taranaki Bight, TTR envisages deploying seabed dredges that pump a slurry of sediment and seawater to their offshore beneficiation plant. This plant will screen the slurry to remove  $>2$  mm particles and then extract and concentrate vanadium-titanomagnetite with alternating steps of magnetic separation and grinding. TTR plans to grind iron sand particles to  $150\text{ }\mu\text{m}$  (first grind) and  $75\text{ }\mu\text{m}$  (second grind) with IsaMill™ technology. Each of the processing steps aboard the beneficiation plant results in tailings and loss of seawater. In the final step, TTR will use freshwater to rinse chlorides from the concentrated iron ore. They will return the de-ored sediment to the seafloor and transfer the concentrated iron ore to a storage vessel. This ore will eventually be transhipped to a capsize vessel for export to customers.

The proposed mining operation involves two activities that may result in the release of contaminants into the water column of South Taranaki Bight. (1) TTR will displace and suspend anoxic sediment from depths up to 15 m below the seafloor (50–100 million tons per year for 10–20 years, A. Sommerville pers. comm.). Suspension of this sediment may mobilise trace metals. (2) Aboard their beneficiation plant, TTR will grind the suspended sediment increasing its specific surface area and so the potential for the release of trace metals into the seawater tailings.

One mechanism mobilising trace metals involves the oxidation of metal sulfides. Most trace metals, however, do not form distinct sulfides but adsorb onto pyrite and iron monosulfides, the most abundant solid sulfide phases in marine sediments. Oxidation of these sulfide phases upon contact with oxygenated seawater may release the adsorbed trace metals making them available for benthic and pelagic biota.

The oxidation rates of iron and other metal monosulfides are measured in hours (Burton et al. 2006); pyrite ( $FeS_2$ ) oxidation rates, however, are measured in months, although some pyrite fractions can oxidise in less than a few days (Morse, 1994). Such slow oxidation of pyrite may alter the bioavailability of metals in the pore water of deep sediment that has been displaced to the surface of the seafloor but less so in “short-lived” suspensions of this sediment in seawater. In such suspensions, oxidation

of iron monosulfides, measured as so-called acid volatile sulfides (AVS), will be a more important factor in increasing metal bioavailability (for a critical discussion of the AVS concept, see Morse and Rickard 2004; ANZECC & ARMCANZ 2000).

**Figure 1. Map showing the location of the proposed iron sand mining area in South Taranaki Bight, North Island, New Zealand.**

To assess the potential of their mining operation for causing adverse effects, TTR contracted Auckland University of Technology (AUT) to conduct a series of laboratory tests to investigate as a function of depth below the seafloor (1) selected physical

properties of the target sediment, (2) the sediment content of acid volatile sulfides and simultaneously extracted trace metals, and (3) the concentrations of trace metals in suspensions of sediment in seawater. Furthermore, TTR contracted AUT to investigate if grinding enriched iron sand increases the potential of this sand to release trace metals when suspended in seawater.

The objectives of this investigation were as follows:

#### *Section A*

1. Describe selected properties of the target sediments: particle size distribution, water content, organic matter content, acid volatile sulfide content, and simultaneously extracted metal content (cadmium, chromium, copper, lead, nickel, and zinc).
2. Evaluate trace metal concentrations (cadmium, chromium, copper, lead, nickel, and zinc) in seawater suspensions of the target sediments.

#### *Section B*

3. Investigate if grinding of magnetically enriched iron sand increases the potential of the iron sand to release trace metals when suspended in seawater.

# Material and methods

## Approach

### *Section A*

We conducted physicochemical analyses and standard elutriate tests on sediment collected at five sites within the proposed mining area from sediment depths up to 5 m (Table 1). Reference sediment comprised South Taranaki Bight sediment collected at the same sites from the surface of the seafloor. This sediment is subject to resuspension by waves and currents and any release of trace metals represents natural background processes. Furthermore, we analysed slurries of sediment collected at two additional sites within the proposed mining area from sediment depths up to 18 m (Table 1).

### *Section B*

TTR provided a sample of processed (enriched) iron sand, part of which we ball-milled to produce three particle size fractions. We used these fractions and a sample of the as-received iron sand to conduct physicochemical analyses and standard elutriate tests.

## Sample collection and preparation

### *South Taranaki Bight sediment*

TTR collected one sediment core and 20 L of seawater at each of five sites within the proposed mining area on the 12<sup>th</sup> and 13<sup>th</sup> of June 2012, and sediment slurry and 20 L of seawater at each of two sites on the 26<sup>th</sup> and 27<sup>th</sup> of February 2013 (Table 1).

**Table 1. Geographic coordinates and water depth (m) of seven sampling sites. At sites C1–3 and D2–3, the recorded penetration depth of the coring tube (PD) exceeded the length of the retrieved sediment core (CL). PD and CL were linearly correlated:  $CL = 0.981 \times PD - 0.802$  ( $R^2 = 0.982$ ). VC, vibrocorer; RC, reverse circulation corer.**

ID	Mining field	Sampling Device	Sample Type	Latitude	Longitude	Water depth (m)	PD (m)	CL (m)
C1	Christina	VC	Core	S 39° 53.637'	E 174° 6.696'	38	4.3	3.6
C2	Christina	VC	Core	S 39° 53.560'	E 174° 4.565'	40	5.0	4.1
C3	Christina	VC	Core	S 39° 52.128'	E 174° 3.268'	43	3.0	2.2
C4	Christina	RC	Slurry	S 39° 53.161'	E 174° 4.192'	42	18	-
D2	Diana	VC	Core	S 39° 52.636'	E 174° 7.744'	32	3.2	2.2
D3	Diana	VC	Core	S 39° 52.003'	E 174° 6.775'	37	5.0	4.0
D4	Diana	RC	Slurry	S 39° 52.431'	E 174° 6.898'	38	18	-

The sampling sites are located ~32 km offshore within an area of ~3.5 km diameter. Four sites are located within the proposed mining field *Christina* (C1–C4, 38–43 m water depth); three sites are located in the proposed mining field *Diana* (D2–4; 32–38 m water depth).

(i) Vibrocoreing

To collect a sediment core, TTR deployed an underwater electrical vibrocorer (Model P-5b, Rossfelder Corporation) seated in a custom-built rigid frame. They lowered this frame to the seafloor from the vessel *Islander Leader II* with a pivoting A-frame, a winch line and the vibrocorer's electrical cable.

The vibrocorer consists of a pair of vibrator motors in a contra-rotating configuration that pushes a stainless-steel core tube into the seafloor (ID = 9.7 cm, 2 mm wall thickness, length = 5 m). The core tube is fitted with a 3 mm internal Teflon lining (OD = 9.6 cm) and a core nose with fingered (orange-peel) core catcher.

**Table 2. Sediment core subsampling and sample identification.**

Site ID	Sediment depth (m)	Core depth (m)	Sample ID

D3	4	3.2	D3-4-A	D3-4-B
D3	5	4.0	D3-5-A	D3-5-B

After returning to Port Wanganui, we hydraulically extruded all five Teflon-liners and enclosed sediment cores from their stainless steel tubes. We then cut the liners into sections (0–1.5, 1.5–2.5, 2.5–3.5, and 3.5–5 m), airtight sealed the ends of each section with plastic bags and transported them to Auckland on ice. In Auckland, the sections were stored in a refrigerated container at -20°C until sediment analyses commenced.

Inspection of the contents of the sections of Teflon liner revealed that, for each sampling site, the recorded penetration depth (PD) of the stainless-steel coring tube exceeded the length of the retrieved sediment core (CL) suggesting that the sediment had been compressed during coring. PD and CL were linearly correlated:  $CL = 0.981 \times PD - 0.802$  ( $R^2 = 0.982$ ).

We used this correlation to calculate the distances from the core surface (core depth, Table 2) that corresponded to sediment depths of 0, 1, 2, 3, 4, and 5 m and then removed two aliquots of sediment (samples A, B) at each distance. Each aliquot was filled into one 500 mL HDPE sample jar. Sample A was used for sediment elutriation tests; sample B provided sediment for the determination of organic matter content, particle size distribution, acid volatile sulfides, and simultaneously extracted metals.

All sample jars used here and in the analyses described below were rinsed with tap water, then 100 mL of 10% v/v nitric acid followed by 300 mL of deionised water and allowed to drain. The jars were then placed in a cupboard and allowed to air dry until used.

#### (ii) Reverse-circulation drilling (RC)

To collect sediment from depths greater than 5 m, TTR deployed a diver-operated reverse-circulation-drill (RC) rig from the vessel PGM Pride once in each of the mining fields *Diana* and *Christina*.

The rig uses water from the sea surface as a drilling lubricant and transport medium. It pumps this seawater under high pressure down the outer tube of a triple tube system to suspend sediment mobilised by a tri-cone roller drill bit. High-pressure air pumped through the second tube lifts this sediment through the third tube, the centre tube. A return sample hose connects the centre tube with a cyclone on the vessel's working deck.

The cyclone releases a continuous stream of sediment slurry when the drill descends into the seabed. From this stream, we collected 500 mL aliquots of slurry (in HDPE sample jars, see above) at depth increments of one metre until the drill reached the maximum depth of 18 m. Furthermore, at each of the two drill sites, we filled one 20 L-container with seawater from sea surface.

We transported the samples of slurry and surface seawater to the laboratory on ice, where they were stored at -20°C until analyses commenced.

### *Magnetically enriched iron sand*

TTR provided 30 kg of dry iron sand which had been screened to remove >2 mm particles and then concentrated by means of one medium-intensity and two low-intensity magnetic separation steps.

We used a Retsch Planetary Ball Mill (PM 100) to produce three particle size fractions of this sand—a coarse fraction (BL-C), a medium fraction (BL-M), and a fine fraction (BL-F)—and submitted five aliquots of each fraction for analysis (see below). The Planetary Ball Mill was equipped with a 500 mL sintered aluminium oxide jar and 90 sintered aluminium oxide 10-mm balls. It was operated at 300 rpm.

In addition to the above samples, we removed five  $400 \pm 10$  g samples from the as-received dry iron sand, placed each of these samples in a 500 mL HDPE sample jar (sample ID, as received = BLR), and submitted them for analyses.

### Ball milling

Initial ball-milling trials revealed the approximate milling conditions needed to achieve mean particle sizes of approximately 200 (coarse), 100 (medium), and 30  $\mu$ m (fine). The iron sand as received consisted of particles between 100 and 200  $\mu$ m with minor percentages of smaller and larger particles.

The samples were prepared as follows:

BL-C, coarse sand: we dry-milled five  $400 \pm 10$  g samples with 90 balls for two minutes. This milling was intended to fracture the large particles but have only a minor effect on the smaller particles to give a suitable coarse sample.

BL-M, medium sand: we milled seven  $300 \pm 10$  g samples, each with an added 75 mL of synthetic seawater (to give a 20% by weight mixture) with 90 balls for 10 min. We made synthetic seawater from a 3% w/w solution of analytical reagent grade sodium chloride (Sharlau, SO0227005P) in milli-Q water. The resulting pastes were transferred to acid-washed beakers and dried for 2 h in a fan oven at an indicated 105°C, cooled for 30 min. Thereafter, we separated balls from the milled sand and used a repeated milling for 30 sec to break up the small lumps. Finally, we combined all samples into a composite and then sealed five  $400 \pm 10$  g subsamples of this composite into the sample jars for analysis.

BL-F, fine fraction: we milled seven  $300 \pm 10$  g samples each with an added 75 mL of synthetic seawater (to give a 20% by weight mixture) with 90 balls for 30 min. The resulting pastes were treated as described above. We combined all samples into a composite and then sealed five  $350 \pm 10$  g subsamples of this composite into the sample jars for analysis.

## Analyses

### *Particle size, organic matter and water content*

The size distribution of sediment particles was measured with a laser particle size analyser (Malvern Mastersizer 2000). We determined sediment organic matter content as weight loss after combustion in a furnace for 6 h at 400°C, and sediment water content after drying the sediment at 90°C for 24 h.

### *Sediment extractions: AVS*

Acid volatile sulfides (AVS): We followed the method described in Wilson and Vopel (2012). We removed four aliquots (about 5 g) from each homogenised sediment sample and added each aliquot to a 40 mL glass vial containing 30 mL deoxygenated HCl (1 mol L<sup>-1</sup>, ACS grade). The vial was closed with an airtight lid and briefly shaken; the extraction lasted one hour. We weighed each HCl filled vial before and after adding sediment to determine the exact mass of sediment used in the extraction.

To measure the concentration of H<sub>2</sub>S in the HCl extractant, we used an amperometric H<sub>2</sub>S microelectrode (Unisense A/S, 500-µm tip diameter, response time ~1 sec). The microelectrode is filled with a ferricyanide solution (K<sub>3</sub>[Fe(CN)<sub>6</sub>]) that is reduced to ferrocyanide (K<sub>4</sub>[Fe(CN)<sub>6</sub>]) in the presence of H<sub>2</sub>S, which diffuses from the surrounding HCl extractant through the silicone membrane of the microelectrode tip (Jeroschewski 1996; Kühl et al. 1998). Re-oxidation of the reduced ferrocyanide produces a current that is linearly proportional to the concentration of H<sub>2</sub>S.

We calibrated the microelectrode with freshly prepared sulfide standards. To prepare the standards, 0, 150, and 300 µmol L<sup>-1</sup>, aliquots of a stock solution of Na<sub>2</sub>S 9H<sub>2</sub>O (0.1 mol L<sup>-1</sup>) were added to 30 mL deoxygenated HCl (1 mol L<sup>-1</sup>). The concentration of sulfide in the stock solution was measured by iodometric titration using standard iodine (0.05 mol L<sup>-1</sup>) and sodium thiosulfate (0.1 mol L<sup>-1</sup>) solutions (Vogel 1989).

### *Sediment extractions: trace metals*

**Sediment core samples:** 10 mL HCl were removed from each of four repeated AVS extracts of each of 28 sediment sample (see above), filtered (0.45 µm), and combined in one 40 mL vial. We sent the 28 combined samples to Hill Laboratories for analyses of cadmium, chromium, copper, lead, nickel, and zinc concentrations (ICP-MS, screen level, APHA 3125B 21<sup>st</sup> ed. 2005, see Appendix for Hill Laboratories Analysis Report, No 1030579).

**Processed iron sand samples:** The Australian Government National Measurement Institute (hereafter, NMI) digested the samples of processed iron sand with 1 M HCl for two hours and determined the concentration of trace metals with high resolution ICP-MS (Finnigan Element 2, method NT 2.49, ANZECC Guidelines 2000, Section 3.5.5, NMI Report No RN0981498).

### *Standard elutriation*

The elutriation methods used by Hill Laboratories and NMI are based on the ANZECC Interim Ocean Disposal Guideline Section 3.4.2 and USEPA Evaluation of Dredged Material Proposed for Ocean Disposal – Testing Manual, Section 10.1.2.1.

**Sediment core samples:** Hill Laboratories suspended 23 samples of South Taranaki Bight sediment in seawater from South Taranaki Bight. To do so, they combined the sediment with seawater in a ratio of 1:4 by volumetric displacement. The mixture was stirred vigorously for 30 min and then allowed to settle for one hour.

**Processed iron sand samples:** NMI suspended 20 mL of each of 20 samples of processed iron sand in 80 mL artificial seawater (method NW.SL17, NMI Report No RN0981494). To facilitate reproducibility and to maximise contact between the solid and liquid phase, a TCLP end-over-end tumbler was used to stir the suspension 30 min before it was allowed to settle for one hour.

### *Standard elutriate test*

**Sediment core samples:** Hill Laboratories centrifuging the supernatant seawater to remove particulates and then measured the concentrations of dissolved cadmium, chromium, copper, lead, nickel, and zinc (nitric acid digestion, ICP-MS, APHA 3125B 21<sup>st</sup> ed. 2005). Samples of filtered seawater from South Taranaki Bight were analysed separately to assess background trace metal concentrations.

**Processed iron sand samples:** NMI used high resolution ICP-MS (Finnigan Element 2) for the determination of cadmium, chromium, copper, lead, nickel, and zinc in the elutriate (NMI Method NT 2.47). Four samples of synthetic seawater were analysed separately to assess background trace metal concentrations.

### *Trace metals in sediment slurry*

Hill Laboratories collected and filtered (0.45 µm membrane) aliquots of seawater from all RC slurry samples, preserved these aliquots with nitric acid (APHA 3030 B 21<sup>st</sup> ed. 2005) and then measured the concentrations of dissolved chromium and nickel (ICP-MS, APHA 3125B 21<sup>st</sup> ed. 2005).

# Results and discussion

## Section A: sediment cores and slurry

### *Sediment properties and AVS content*

With our analyses of core sediment, we assess the sediment grain size and the sediment contents of acid volatile sulfides (AVS), simultaneously extracted metals (SEM) and organic matter as a function of sediment depth below the seafloor. Furthermore, we compare these properties with the properties of reference sediment collected from the surface of the seafloor.

**Table 3. Granulometric analyses of sediment core samples. Mass median diameter [d(0.5),  $\mu\text{m}$ ], mean diameter ( $\mu\text{m}$ ), mode ( $\mu\text{m}$ ), standard deviation (SD), kurtosis (Ks), skewness (Sk), and proportion larger than 2 mm (%) of sediment particles at sites C1-C3, D2, D3.**

<sup>1</sup>Kurtosis is the measure of peakedness (width of peak) or flatness of the distribution related to normal distribution.

<sup>2</sup>Skewness is a measure of the asymmetry of the particle size frequency distribution.

The mean particle diameter of sediment from mining field *Christina* ranged from 221 to 471  $\mu\text{m}$  (sample IDs: C1–C3, Table 3). We classify this sediment as medium sand

(ISO 14688-1). The range of particle sizes was smaller in sediment samples from mining field *Diana* (sample IDs: D2, D3); here the mean particle diameter was between 223 and 291  $\mu\text{m}$ . With the exception of site C3, the size of sediment particles decreased from the surface of the sediment to a depth of two meter. Deeper, however, particles increased in size at site C2 (4 and 5 m depth) and D3 (5 m depth).

**Table 4. Acid volatile sulfides (AVS) content ( $\text{nmol g}^{-1}$  wet weight), water content (% wet weight) and organic matter content (OM, % dry weight) of sediment in the proposed South Taranaki Bight mining area.**

Site ID	Sediment depth (m)	AVS ( $\text{nmol g}^{-1}$ ww)	Water content (% ww)	OM content (% dw)
C1	0	9.6	13	0.71
C1	1	6.7	18	0.88
C1	2	10.6	15	0.92
C1	3	6.6	16	0.93
C1	4	13.2	16	0.57
C2	0	5.5	17	0.87
C2	1	4.3	19	0.83
C2	2	12.3	19	0.85
C2	3	10.0	18	0.88
C2	4	5.8	16	0.63
C2	5	9.8	12	0.31

D3	4	32.6	20	0.89
D3	5	4.8	17	0.82

There was no evidence for a consistent change with increasing depth below the seafloor in sediment organic matter, water and acid volatile sulfide contents in the two proposed mining fields. The sediment pore water contributed 12–20% to the sediment wet weight and the contribution of organic matter to the sediment dry weight was generally below one percent (Table 4). Note that the organic matter content of sediment at site D2 was about half of that of sediment at the nearby site D3; the reason for this difference is unknown.

The low sediment organic matter contents in mining fields *Christina* and *Diana* explain the generally low sediment AVS contents ( $\sim 9 \mu\text{mol kg}^{-1}$ , Table 4). Sediment from three

meter depth at site D3 makes an exception; here the AVS concentration was an order of magnitude higher.

### *Simultaneously extracted metals*

We extracted trace metals from the deep anoxic sediments to assess the likelihood of adverse effects on the benthic biota should this sediment be exposed by removal of the overlying sediment or otherwise displaced to the surface of the seafloor. To do so, we compare the trace metal concentration in the dilute-acid extracts from the deep sediment with that in extracts from surface (reference) sediment. We argue that adverse effects of trace metals on the functioning of the benthic ecosystem are unlikely if the dilute-acid soluble metal concentration in the deep sediment is of the same order of magnitude than that in the reference sediment.

**Table 5. Concentration of simultaneously (dilute-acid) extracted metals (mg kg<sup>-1</sup> dry weight) in the sediment of the proposed mining area in South Taranaki Bight. Ref, reference sediment.**

An alternative approach compares concentrations of metals extracted with strong acid (total metal concentration) against ANZECC & ARMCANZ (2000) interim sediment quality guidelines (ISQG). The ISQG-low and -high values, which correspond to the

effects range-low and -median used in the NOAA listings (Long et al. 1995), represent a statistical probability of effects when tested against one or two species, usually amphipods. The values do not, however, consider antagonism or synergism between chemicals. Note that ANZECC & ARMCANZ (2000) acknowledges the dilute-acid-soluble metal concentration as a more meaningful measure than the total metal concentration and that derivations of future guidelines might ultimately be based on dilute-acid-soluble metal concentration.

The concentrations of dilute-acid soluble cadmium, copper, lead and zinc in deep sediment were of the same order of magnitude as their maximum concentrations in surface (reference) sediment (Table 5). For dilute-acid soluble cadmium, copper and zinc, there was no evidence for consistent trend of increasing concentrations with increasing sediment depth below the seafloor. The sediment concentrations of lead decreased with depth below the seafloor at sites C1, C2 and D3. We infer a low probability of adverse effects of these dilute-acid soluble metals on benthic ecosystem functioning.

The concentrations of dilute-acid soluble chromium and nickel in deep sediment were often one order of magnitude higher than their maximum concentrations in surface (reference) sediment (Table 5). At sites C1, C3, D2, and D3, chromium and nickel concentrations increased with increasing depth below the seafloor. Because TTR's mining operation will likely extend beyond 5 m depth, the maximum depth measured, this trend initiated additional tests with slurries of sediment from depth below the seafloor of up to 18 m (see below, RC slurry analyses).

For both metals, nickel and chromium, the majority of the dilute-acid soluble fraction is likely not associated with the AVS fraction. For example, if the average dilute-acid soluble nickel concentration in sediment of the mining field *Christina* is taken around  $9 \text{ mg kg}^{-1}$ , this corresponds to  $\sim 152 \text{ } \mu\text{mol kg}^{-1}$ . The corresponding sediment AVS content, however, does not exceed  $\sim 13 \text{ } \mu\text{mol kg}^{-1}$ , which is >10-times less than the concentration of nickel. That is, the majority of dilute-acid soluble nickel is likely not associated with the AVS fraction and oxidation of AVS upon resuspension of anoxic sediment may not be responsible for any elevated concentration in the sediment suspension.

#### *Trace metals in sediment suspensions*

In the following we compare the results of our elutriate tests against ANZECC & ARMCANZ water quality guidelines for toxicants (ANZECC & ARMCANZ 2000). These guidelines were mainly derived from laboratory tests in clean water and calculated at four different protection levels, 99, 95, 90 and 80% (Table 6). The protection levels signify the percentage of species expected to be protected.

The guidelines represent the best current estimates of the concentrations of chemicals that should have no significant adverse effects on the aquatic ecosystem. Note, however, that these guidelines are not blanket guidelines; variations in types of

ecosystems can affect transport, dilution and degradation of chemicals, and so their bioavailability and toxicity.

The guidelines for toxicants were derived with a statistical distribution approach, modified from Aldenberg and Slob (1993), based on calculations of a probability distribution of aquatic toxicity end-points (ANZECC & ARMCANZ 2000). It attempts to protect a percentage of species, usually 95%, a protection level that is commonly applied to ecosystems classified as slightly or moderately disturbed.

We compare the results of our elutriate tests against guidelines for the 95 and 99% protection level. We include the highest protection level (99%) because we consider (i) South Taranaki Bight as undisturbed ecosystem and (ii) the general lack of biological and chemical baseline data for this particular environment.

**Table 6. ANZECC & ARMCANZ guidelines ( $\text{g m}^{-3}$ ) for six trace metals at alternative levels of protection of species (ANZECC & ARMCANZ 2000).**

Level of protection (% species)	Cd	Cr III	Cu	Pb	Ni	Zn
99%	0.0007 <sup>B</sup>	0.0077	0.0003	0.0022	0.007	0.007
95%	0.0055 <sup>B, C</sup>	0.0274	0.0013	0.0044	0.070 <sup>C</sup>	0.015 <sup>C</sup>
90%	0.0140 <sup>B, C</sup>	0.0486	0.003 <sup>C</sup>	0.0066 <sup>C</sup>	0.200 <sup>A</sup>	0.023 <sup>C</sup>
80%	0.0360 <sup>A, B</sup>	0.0906	0.008 <sup>A</sup>	0.0120 <sup>C</sup>	0.560 <sup>A</sup>	0.043 <sup>C</sup>

A = Figure may not protect key test species from acute toxicity (and chronic)—check NWQMS, No. 4, Section 8.3.7 for spread of data and its significance. 'A' indicates that trigger value > acute toxicity figure; note that trigger value should be <1/3 of acute figure (NWQMS, No. 4, Section 8.3.4.4).

B = Chemicals for which possible bioaccumulation and secondary poisoning effects should be considered (see NWQMS, No. 4, Sections 8.3.3.4 and 8.3.5.7).

C = Figure may not protect key test species from chronic toxicity (this refers to experimental chronic figures or geometric mean for species)—check NWQMS, No. 4, Section 8.3.7 for spread of data and its significance.

Our standard elutriate test revealed that,

(1) For all metals except nickel, the concentration in the elutriate extract were either below detection limit (chromium, copper, lead, zinc) or, if a metal was detected, concentrations did not exceed the ANZECC & ARMCANZ guideline concentrations for the protection of 99% of species (cadmium, Table 7). Note that for copper, the detection limit was below the guidelines for the protection of 95% of species.

(2) The concentrations of nickel in the elutriate extracts of deep sediments (all sites) and surface (reference) sediment (sites C2, C3, D2) were equal or larger than the ANZECC & ARMCANZ guideline concentrations for the protection of 99% of species

(Table 7). However, the nickel concentration never exceeded the ANZECC & ARMCANZ guideline concentrations for the protection of 95% of species.

The concentration of nickel in the South Taranaki Bight seawater was consistently below detection limit (Table 7). Assuming that this nickel concentration equals the detection limit for nickel ( $0.0063 \text{ g m}^{-3}$ ), an only 83-fold dilution of the elutriate extract would decrease the highest nickel concentration measured ( $0.065 \text{ g m}^{-3}$ ) to below ANZECC & ARMCANZ guideline concentrations for the protection of 99% of species.

**Table 7. Concentrations of six trace metals in seawater and sediment elutriates ( $\text{g m}^{-3}$ ). Numbers in parenthesis represent the limits of detection (LOD,  $\text{g m}^{-3}$ ). <LOD, below limits of detection. Note that for all metals except Cu, the detection limits were below the ANZECC & ARMCANZ guidelines for the protection of 99% of species. For Cu, the detection limit was below the guidelines for the protection of 95% of species.**

### Chromium and nickel in RC slurry

We used sediment slurry to assess the potential release of nickel and chromium from sediment deeper than five meter below the surface of the seafloor. We did so because the above described SEM analyses revealed that the nickel and chromium content of the sediment at four of the five sites (C1, C3, D2, and D3) increased from the surface to five meter below the surface of the seafloor (see Table 5).

A repeat of the above described SEM analyses with sediment from greater depth was not possible because TTR's vibrocorer collects cores of undisturbed sediment to a maximum depth below the seafloor of only five meter. TTR's reverse-circulation drill, however, provided sediment from greater depth but this sediment reached the surface in form of a slurry, a mixture of seawater, air and sediment.

We note that the concentration of dilute-acid soluble nickel in core sediment (Table 5) and the concentration of nickel in the elutriate extract of this sediment (Table 7) were linearly correlated ( $R^2 = 0.837$ ). If this correlation holds for sediment from >5 m depth below the seafloor, then an increase with depth in the sediment content of dilute-acid soluble metal should cause an increase with depth in the concentration of metals in slurry of this sediment.

**Table 8. Concentrations of nickel and chromium in RC sediment slurry ( $\text{g m}^{-3}$ ) from the proposed mining fields *Diana* and *Christina*. Numbers in parenthesis represent the limits of detection (LOD,  $\text{g m}^{-3}$ ). <LOD, below limits of detection.**

Following this logic, we analysed RC slurry of sediment from mining fields *Diana* and *Christina* sampled in one-metre increments starting one metre below the surface of the seafloor to a maximum depth of 18 m. This analysis failed to reveal evidence for a trend of increasing metal concentrations with increasing sediment depth below the seafloor. That is, we found no consistent increase with depth in the concentrations of dissolved nickel. The concentrations of chromium were below detection limit.

## Section B: processed iron sand

With their offshore beneficiation plant, TTR plans to extract and concentrate vanadium-titanomagnetite with alternating steps of magnetic separation and grinding. TTR will keep the sediment suspended in seawater to feed it through a series of grinding mills. This seawater, and any dissolved trace metals released from the sediment particles during grinding, will eventually be returned to South Taranaki Bight.

**Table 10. Processed iron sand. Characteristics of particle size frequency distributions. [d(0.5)], mass median diameter (µm); Mean, mean diameter (µm); Mode (µm), SD, ±1 standard deviation (µm); Ks, kurtosis; Sk, skewness.**

<sup>1</sup>Kurtosis is the measure of peakedness (width of peak) or flatness of the distribution related to normal distribution.

<sup>2</sup>Skewness is a measure of the asymmetry of the particle size frequency distribution.

The following analyses assist us to assess the potential of grinding sediment particles to affect the concentration of trace metals in the seawater that suspends such particles. To do so, we ask if grinding changes (i) the dilute-acid soluble metal content of magnetically enriched iron sand and (ii) the concentrations of trace metals in elutriates of such iron sand. To include a range of possible grain sizes, we conducted our analyses on four sediment fractions (as received iron sand, coarse grind, medium grind, and fine grind), which we characterise by granulometric analyses.

### *Sediment properties*

We found that the average mass median diameters of the as-received iron sand ( $287 \pm 4 \mu\text{m}$ ) and the coarse sand fraction of the first grind (BL-C,  $276 \pm 19 \mu\text{m}$ ) did not differ significantly. The first grind, however, decreased kurtosis and skewness of the iron sand particle size distribution (Table 10).

Our second grind (BL-M) lowered the average mass median diameter by ~33% to  $186 \pm 8 \mu\text{m}$  and again decreased kurtosis and skewness of the particle size distribution. The third grind (BL-F) decreased the average mass diameter by an order of magnitude to  $23 \pm 3 \mu\text{m}$ ; kurtosis and skewness of the particle size distribution, however, increased by two and one order of magnitude, respectively.

**Table 11. Concentrations of simultaneously extracted metals ( $\text{mg kg}^{-1}$  dry weight) in processed South Taranaki Bight sediment. NMI reporting limits =  $0.5 \text{ mg kg}^{-1}$  dry weight. <LOR, below NMI reporting limits.**

### *Simultaneously extracted metals*

We extracted dilute-acid soluble trace metals from as-received and ball-milled iron sand to assess the effect of grinding on the metal content of the magnetically enriched iron sand.

The extracts of the magnetically enriched iron sands (Table 11) contained two orders of magnitude higher concentrations of zinc and copper than the extracts of natural “unprocessed” sediment analysed in Section A (Table 5). These differences, which may have resulted from differences in the extraction procedure (see Material and methods), are irrelevant because we do not compare the dilute-acid soluble metal contents of “natural sediment” and magnetically enriched iron sand.

Furthermore, note that we do not attempt to assess potential adverse effects of the magnetically enriched (and ball-milled) iron sand on benthic biota (as in Section A) but instead simply ask if the dilute-acid soluble metal content of this iron sand changes through grinding. (Processed iron sand will not be returned to the seafloor but shipped to customers). That is, we compare the dilute-acid soluble metal content of raw and ground magnetically enriched iron sands.

If grinding increases the dilute-acid soluble metal content of the iron sand, then we can expect an increase in the metal content of the seawater elutriates of this iron sand. Such increase would be of interest because the seawater that suspends and feeds iron sand through the TTR’s grinding mills eventually returns to South Taranaki Bight.

Our analyses showed that the average concentrations in magnetically enriched iron sand of dilute-acid soluble chromium, nickel and zinc decreased after each of the first two grinds (average  $d(0.5) = 242$  and  $172\ \mu\text{m}$ ) but increased after the third grind (average  $d(0.5) = 11\ \mu\text{m}$ ) to 171, 150, and 162% of that in the extract of the as-received (raw) iron sand (average  $d(0.5) = 252\ \mu\text{m}$ , Table 11).

In contrast, for copper and lead, the average concentrations in the extracts of the first two grinds did not significantly differ from that of the as-received iron sand but the third grind increased these concentrations to 193 and 132% of the concentration in the extract of the as-received iron sand. Because TTR plans to grind their iron sand particles to sizes less than  $172\ \mu\text{m}$  (our second grind), their final product will likely contain a larger content of these dilute-acid soluble trace metals.

The concentrations of dilute-acid soluble cadmium were below reporting limits in both raw and ball-milled magnetically enriched iron sand.

### *Trace metals in sediment suspensions*

Our elutriate tests revealed concentrations of cadmium, lead and nickel below the limits of reporting for all sediment samples (Table 12). Chromium was detected only in

the fine sediment fraction but its average concentration was below the ANZECC & ARMCANZ guideline for the protection of 99% of species.

We detected zinc in the elutriates of all sediment samples but the concentration averages for each sand size fraction did not exceed the ANZECC & ARMCANZ guideline for the protection of 99% of species (Tables 12).

The elutriate concentration of copper was negatively linearly correlated ( $r = -0.89$ , outlier BL-M1 excluded) with the particle size of the suspended iron sand. That is, the concentration of copper in iron sand suspensions increased with decreasing size of the suspended iron sand particles.

**Table 12. Concentrations of six trace metals in synthetic seawater (Syn sw) and synthetic seawater elutriates of processed sediment ( $\text{g m}^{-3}$ ). Numbers in parenthesis represent Limits of Reporting (LOR,  $\text{g m}^{-3}$ ). <LOR, below Limits of Reporting. Note that for all metals except Cu, the LOR were below the ANZECC & ARMCANZ guidelines for the protection of 99% of species. For Cu, the LOR was below the guidelines for the protection of 95% of species.**

The average elutriate copper concentrations of as-received and coarse iron sand ( $0.0013 \text{ g m}^{-3}$ ) exceeded the ANZECC & ARM CANZ guideline for the protection of 99% of species. Assuming that South Taranaki Bight seawater contains  $0.00025 \text{ g m}^{-3}$  (0.25 ppb) copper an only 20-fold dilution would decrease this concentration to below the concentration limit for the protection of 99% of species (Table 6).

The average copper concentrations in the elutriates of medium and fine coarse iron sand ( $0.0081$  and  $0.0078 \text{ g m}^{-3}$ ) exceeded the ANZECC & ARM CANZ guideline for the protection of 80% of species. Here, a 160-fold dilution would decrease these concentrations to below the concentration limit for the protection of 99% of species.

## Summary and conclusions

As expected for high-energy offshore environments, the low organic matter content (<1% dry weight) of the medium sand in the mining areas explained the low sediment content of acid volatile sulfides (AVS). We found no evidence for an increase with depth below the seafloor in sediment organic matter and AVS contents.

### *Dilute-acid soluble metals in deep sediment*

The concentrations of dilute-acid soluble cadmium, copper, lead and zinc in deep sediment were of the same order of magnitude as their maximum concentrations in surface (reference) sediment. For dilute-acid soluble cadmium, copper and zinc, there was no evidence for a trend of increasing concentrations with increasing sediment depth below the seafloor. The sediment concentrations of lead decreased with depth below the seafloor at sites C1, C2 and D3. We infer a low probability of adverse effects of these dilute-acid soluble metals on benthic ecosystem functioning.

The concentrations of dilute-acid soluble chromium and nickel in deep sediment were often one order of magnitude higher than their maximum concentrations in surface (reference) sediment. Furthermore, at sites C1, C3, D2, and D3, chromium and nickel concentrations increased with increasing depth below the seafloor. Additional analyses of sediment slurry collected to a maximum sediment depth of 18 m, however, did not reveal evidence for such trends. We found no consistent increase with depth in the concentrations of dissolved nickel in the slurry. The concentrations of chromium were below the detection limit.

### *Trace metals in sediment suspensions*

For all metals except nickel, the concentrations in the elutriate extract were either below detection limit (chromium, copper, lead, zinc) or, if a metal was detected (cadmium), concentrations did not exceed the ANZECC & ARM CANZ guideline concentrations for the protection of 99% of species. The detection limit for copper was below the guidelines for the protection of 95% of species.

The concentrations of nickel in the elutriate extracts of deep sediments (all sites) and surface (reference) sediment (sites C2, C3, D2) were equal or larger than the ANZECC & ARMCANZ guideline concentrations for the protection of 99% of species. However, the concentration never exceeded the guideline concentrations for the protection of 95% of species. Assuming that the nickel concentration in South Taranaki Bight seawater equals the detection limit for nickel, it would only require an 83-fold dilution of the elutriate extract to decrease the highest nickel concentration measured to below guideline concentrations for the protection of 99% of species.

#### *Effect of grinding on the dilute-acid soluble metal content of enriched iron sand*

A sample of magnetically enriched iron sand was ball milled to three average sizes, 276 µm, 183 µm and 23 µm. The average concentrations in this iron sand of dilute-acid soluble chromium, nickel and zinc decreased after each of the first two grinds but increased after the third grind to 171, 150, and 162% of that in the extract of the as-received enriched iron sand. In contrast, for copper and lead, the average concentrations in the extracts of the first two grinds did not significantly differ from that of the as-received iron sand but the third grind increased these concentrations to 193 and 132% of the concentration in the extract of the as-received iron sand. The concentrations of dilute-acid soluble cadmium were below reporting limits in both as-received and ball-milled magnetically enriched iron sand.

TTR plans to grind iron sand particles to sizes less than 172 µm (our second grind); this grinding may gradually enrich the recirculated seawater that feeds the iron sand through TTR's grinding mills with trace metals. Our elutriate tests revealed, however, concentrations of cadmium, lead and nickel below the limits of reporting for all sediment samples. Chromium was detected only in the fine sediment fraction; zinc was detected in elutriates of all sediment samples. For both metals, the concentration averages for each sand size fraction did not exceed the ANZECC & ARMCANZ guideline for the protection of 99% of species. We infer a low probability of adverse effects of these metals on ecosystem functioning of the South Taranaki Bight water column.

The elutriate concentration of copper was negatively linearly correlated ( $r = -0.89$ ) with the particle size of the suspended iron sand. The average elutriate copper concentrations of as-received and the coarse iron sand fraction exceeded the ANZECC & ARMCANZ guideline for the protection of 99% of species. Assuming that South Taranaki Bight seawater contains 0.25 ppb copper an only 20-fold dilution would decrease this concentration to below the concentration limit for the protection of 99% of species. In contrast, the average copper concentrations in elutriates of medium and fine coarse iron sand exceeded the guideline for the protection of 80% of species. Here, a 160-fold dilution would decrease these concentrations to below the concentration limit for the protection of 99% of species.

The reported uncertainty is an expanded uncertainty with a level of confidence of approximately 95 percent (i.e. two standard deviations, calculated using a coverage factor of 2). Reported uncertainties are calculated from the performance of typical matrices, and do not include variation due to sampling.

For further information on uncertainty of measurement at Hill Laboratories, refer to the technical note on our website: [www.hill-laboratories.com/files/Intro\\_To\\_UOM.pdf](http://www.hill-laboratories.com/files/Intro_To_UOM.pdf), or contact the laboratory.

## SUMMARY OF METHODS

The following table(s) gives a brief description of the methods used to conduct the analyses for this job. The detection limits given below are those attainable in a relatively clean matrix. Detection limits may be higher for individual samples should insufficient sample be available, or if the matrix requires that dilutions be performed during analysis.

Sample Type: Sediment			
Test	Method Description	Default Detection Limit	Samples
Elutriation testing	Extn with (client supplied) water, eg seawater, Sed:Water 1:4 by vol, mix 30 min, settle 1 hr, filtration or centrifugation. US EPA 503/8-91/001, "Evaluation of Dredged Material for Ocean Disposal".	-	1-28

Sample Type: Aqueous			
Test	Method Description	Default Detection Limit	Samples
Total Digestion of Saline Samples	Nitric acid digestion. APHA 3030 E 21 <sup>st</sup> ed. 2005.	-	29-66
Total Cadmium	Nitric acid digestion, ICP-MS, ultratrace level. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.00021 g/m <sup>3</sup>	29-66
Total Chromium	Nitric acid digestion, ICP-MS with dynamic reaction cell, ultratrace. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.0011 g/m <sup>3</sup>	29-66
Total Copper	Nitric acid digestion, ICP-MS with dynamic reaction cell, ultratrace. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.0011 g/m <sup>3</sup>	29-66
Total Lead	Nitric acid digestion, ICP-MS, ultratrace level. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.0011 g/m <sup>3</sup>	29-66
Total Nickel	Nitric acid digestion, ICP-MS, ultratrace level. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.0063 g/m <sup>3</sup>	29-66
Total Zinc	Nitric acid digestion, ICP-MS with dynamic reaction cell, ultratrace. APHA 3125 B 21 <sup>st</sup> ed. 2005.	0.0042 g/m <sup>3</sup>	29-66

These samples were collected by yourselves (or your agent) and analysed as received at the laboratory.

Samples are held at the laboratory after reporting for a length of time depending on the preservation used and the stability of the analytes being tested. Once the storage period is completed the samples are discarded unless otherwise advised by the client.

This report must not be reproduced, except in full, without the written consent of the signatory.
